HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Abstract: The first dysprosium complexes with a terminal fluoride ligand are obtained as air-stable compounds. The strong, highly electrostatic dysprosium–fluoride bond generates a large axial crystal field splitting of the $J = 15/2$ ground state, as evidenced by high-resolution luminescence spectroscopy and correlated with the single-molecule magnet behavior through experimental magnetic susceptibility data and ab initio calculations.

Since the discovery of single-molecule magnets,[1] the search for improved properties, in particular enhanced thermal barriers to magnetic relaxation and magnetic blocking temperatures, has driven the development of new complexes with magnetic properties customized by coordination environment.[2] This approach has been widely applied for mononuclear lanthanide complexes, wherein the barrier to slow magnetic relaxation originates from splitting of the ground state by the crystal field.[3] Here, manipulation of the crystal field provides a basis for improving single-molecule magnet properties, as analyzed by applying electrostatic models or more elaborate quantum chemistry calculations.[4]

In the case of dysprosium(III), a linear two-coordinate complex provides the ideal coordination environment, with the two ligands serving as anionic point charges that preferably reside as close to the metal center as possible in order to maximize crystal-field splitting.[5] Approximating this synthetically challenging geometry with pseudo-linear complexes possessing strongly-donating axial ligands,[6] such as in the pentagonal bipyramidal complex $[\text{Dy}((\text{BuO})_2\text{py})_2]^+\text{[6]a}$ and sandwich complexes such as $[(\text{Cp})_2\text{Dy}]^+$,[7] prompts a strong axiality of nearly all of the crystal-field-split magnetic doublets. This axiality can lead to impressive relaxation barriers of $U_{\text{exc}} > 1200$ cm$^{-1}$, and, for the latter complex, a record hysteresis temperature of 60 K. In spite of their exceptional magnetic behavior, these complexes are unstable in the presence of air and water, which limits their utility beyond the lab setting. In pursuit of ligands that would engender a similar or even stronger crystal field splitting while showing greater stability to air and water, we selected terminal fluoride as a candidate. We envisioned that a Dy–$(\eta^1\text{-F})$ or $(\eta^1\text{-F})$–Dy–$(\eta^1\text{-F})$ unit stabilized by an appropriate ligand environment would have strong axial anisotropy based on the dominant dysprosium–fluoride electrostatic interaction. Indeed, ab initio calculations performed on the hypothetical $[\text{Dy}–\text{F}]^+$ and $[\text{F}–\text{Dy}–\text{F}]$ units predict a $|M_{J>}| = \pm 15/2$ ground state stabilized by several hundreds of wavenumbers, even with a Dy–F distance arbitrarily fixed to a likely overestimated distance of 2.5 Å.[8]

Synthesis of an idealized low-coordinate lanthanide complex or even heteroleptic complexes with an $\eta^1\text{-F}$ ligand, however, is challenging because of the tendency of the fluoride ligand to either coordinate in a bridging fashion or to form the stable and insoluble LnF$_3$ compounds.[6] Among structurally-characterized mononuclear lanthanide complexes with a terminal fluoride ligand[6] is a tris-(3-(2-pyridyl)pyrazolyl)hydroborate (Tp$^\text{3+}$) complex $[\text{Eu}(\text{Tp}^\text{3+})(\text{py})\text{F}(\text{MeOH})_2]^+$ in which the hexadentate Tp$^\text{3+}$ ligand prevents unwanted aggregation of lanthanide moieties.[9] We thus investigated dysprosium(III) analogues of this type to evaluate whether a single terminal fluoride donor is sufficient to create a large axial crystal field, thereby engendering single-molecule magnet behavior. Here, we report the synthesis of two air-stable compounds, $[\text{Dy}(\text{Tp}^\text{3+})(\text{F}(\text{dioxane}))[\text{PF}_6])$ (1) and $[\text{Dy}(\text{Tp}^\text{3+})(\text{F}(\text{pyridine})_2)[\text{PF}_6])$ (2), and the precise determination of their $^4\text{H}_{15/2}$ ground state crystal field splittings by low-temperature luminescence measurements.[10] Dynamic magnetic susceptibility studies reveal large energy barriers to slow magnetic relaxation that correlate well with the axial crystal field splittings observed by luminescence and predicted by ab initio calculations.

Figure 1. View of one cationic molecular unit forming the one-dimensional chain in compound 1 as determined from single-crystal X-ray diffraction data at 100 K, together with the calculated magnetic anisotropy axis (light blue arrow). Grey, blue, red, purple, green, and light blue spheres represent C, N, O, B, F and Dy atoms, respectively; H atoms are omitted for clarity.

Compound 1 and its yttrium analog 1-Y were synthesized through a modification of a previously reported procedure[10a] and crystallized by slow diffusion of dioxane, affording a 1D coordination compound with bridging dioxane ligands in 36% yield. Complex 2 (resp. 2-Y) was obtained by dissolution of 1...
(resp. 1-Y) in pyridine and crystallization by aerial diffusion of petroleum ether in 40% yield. Detailed experimental procedures and full characterization of these complexes can be found in the Supporting Information. Upon dissolution in d6-methanol, both 1-Y and 2-Y showed clean 1H NMR and 19F NMR spectra, corresponding to the species [Y(Tp6)F(CD3OD)2]2− together with free dioxane (for 1-Y) or pyridine (for 2-Y), confirming complexes composition and purity. Notably, the 19F NMR spectrum showed the expected Y–F coupling, with $J_{Y,F} = 69.4$ Hz.

Single-crystal X-ray diffraction structures obtained for the four compounds revealed that each metal ion is nine-coordinate with one terminal fluoride, the hexadentate Tp6 ligand, and two pyridine or dioxane ligands (see Figures 1 and S3-S5 and Table S1-S2). The resulting geometry is a capped square antiprism. As expected, the fluoride ligand provides the shortest bond to the metal center, due to its hard Lewis base character. For instance, in compound 1, the Dy–F distance is 2.094(4) Å and the next shortest bond distances occur between Dy and the nitrogen atoms of the pyrazolyl rings (Dy–N = 2.472(6) and 2.482(4) Å). The Dy–N(pyridine rings of the Tp6) and Dy–O(dioxane) bond lengths are both longer than 2.53 Å. In the case of 1 (and 1-Y), the metal sits on a mirror plane that includes one pyridylpyrazolyl arm of the Tp6 ligand. Owing to the bridging nature of the dioxane ligands, the compounds crystallize as one-dimensional chains, and in the case of 1 the intrachain Dy–Dy distance is 7.81 Å. In contrast, compounds 2 and 2-Y are mononuclear and the coordination sphere is slightly more distorted due to π-stacking between pyridylpyrazolyl arms of adjacent complexes (Figure S5). The shortest Dy–Dy distance in 2 is 8.46 Å.

Emission spectra were measured on crystalline samples of 1 and 2. For both compounds, two transitions could be observed at room temperature in the accessible range of our instrument, the energies of which correspond well with the expected values for the $^4\text{F}_{9/2} \rightarrow ^4\text{H}_{15/2}$ (~480 nm, 20830 cm−1) and $^4\text{F}_{9/2} \rightarrow ^4\text{H}_{13/2}$ (~575 nm, 17390 cm−1) transitions (Figure 2). Liquid helium cooling substantially improved the spectral resolution, revealing eight (resp. seven) lines for the first (second) transition (Figures 3 and S6-S9), with each line corresponding to a transition to one of the eight (seven) doublets composing the $^4\text{H}_{15/2}$ ($^4\text{H}_{13/2}$) state. The absence of any hot band or additional feature in the low-temperature spectra, which usually complicates the analysis, makes the extraction of crystal field splitting energies for the ground states straightforward (Tables S4-S7). For 1 (resp. 2), the total splitting of the $^4\text{H}_{15/2}$ ground state is 770 cm−1 (790 cm−1) and the first and second excited doublets are situated 318 and 453 cm−1 (335 and 457 cm−1) above the ground state doublet. The energy differences between the two compounds are minimal, indicating that the variation of the two equatorial ligands from O-donors to N-donors has only a small influence on the crystal field splitting, which is dominated by the dysprosium–fluoride interaction. The unambiguous assignment of all eight doublet energies of the $^4\text{H}_{15/2}$ ground state is quite rare, and is made possible here because both complexes combine emission with substantial crystal field splitting.

Ab initio calculations (see computational details in the Supporting Information) were performed based on the molecular structures of 1 and 2, excluding the PF6− counterions and solvate molecules of crystallization. In both cases, the calculated splittings of the ground state are in excellent agreement with the luminescence spectra (Tables S14-S15). For example, in the case of 1, the calculated total splitting of 778 cm−1 and the calculated first excited state energy of 297 cm−1 correspond well with the respective energy spacings of 770 cm−1 and 318 cm−1 determined from the luminescence experiment. Notably, the correlation is also very good between the calculated and experimental splittings of the $^4\text{H}_{13/2}$ state (Figure S27). As experimentally observed, the influence of the equatorial solvent ligands on the calculated ground state splitting is minimal. We were thus able to confidently assign the various magnetic
doublets of 1 based upon the ab initio results, with the ground state, first excited state, and second excited state assigned as rather pure |MΩ| = ±15/2z: 13/2 and ±11/2 states, respectively, while for the other components (3rd to 8th doublets), mixing between states is more substantial. The calculations also indicated that both complexes have a strong magnetic anisotropy, with Landé g factors that are fully axial for the ground doublet (g∥ = 19.81, g⊥ = 0.00 for 1 and g∥ = 19.80, g⊥ = 0.00 for 2) and largely axial for the first excited doublet (g∥ = 16.97, g⊥ = 0.02 for 1 and g∥ = 16.95, g⊥ = 0.06, g∥ = 0.07 for 2), prompting investigation of the magnetic behavior of these compounds.

Compounds 1 and 2 were characterized in the solid state by static (dc) and dynamic (ac) magnetization measurements. The room temperature J\_H\_T values for 1 and 2 (13.75 emu-K-mol\(^{-1}\) and 13.64 emu-K-mol\(^{-1}\), respectively) are slightly lower than the predicted value of 14.17 emu-K-mol\(^{-1}\) for an isolated Dy\(^{3+}\) ion (\(^{6}\)H\(_{15/2}\), S = 5/2, L = 5, and g = 4/3), and are in excellent agreement with the ab initio calculated values of 13.78 emu-K-mol\(^{-1}\) for 1 and 13.80 emu-K-mol\(^{-1}\) for 2 (Figures S10 and S18). The decrease in J\_H\_T observed for both compounds upon lowering the temperature to 20 K is also fairly well reproduced by the calculations, providing further evidence that the ground state sub-level energies are accurately predicted, since this decrease in J\_H\_T reflects thermal depopulation of the crystal-field-split M\(_{S}\) levels. Below 20 K, J\_H\_T exhibits a marked decrease that differs from the predicted behavior, especially in the case of compound 1. We attribute this decrease to the presence of strong dipolar interactions, which probably exist within both compounds, and may be expected to be stronger in 1 due to the shorter Dy\(_{2+}\)-Dy\(_{3+}\) distance.

Ac magnetic susceptibility measurements performed on 1 and 2 revealed peaks in the out-of-phase susceptibility (\(\chi^\prime\)) at temperatures up to 50 and 40 K, respectively, in the absence of an applied dc field. In the case of 2, the low-temperature peaks exhibit little temperature dependence between 2 and 8 K, and as a result the Arrhenius plot of the relaxation times versus inverse temperature shows a plateau at the lowest temperatures (Figure S25). This temperature-independent behavior is consistent with quantum tunneling as the primary magnetic relaxation pathway at very low temperatures. At higher temperatures, the out-of-phase peaks for 2 shift markedly with temperature (Figure S20) and the Arrhenius plot shows a power dependent relationship with temperature, consistent with Raman relaxation. Even at the highest temperatures investigated, a clear linear regime expected for an Orbach relaxation process was not observed. This behavior remained for ac data collected under an applied dc field of 1200 Oe, determined to be the optimal field for slowing down the magnetic relaxation (Figure S23). Even still, we found it was not possible to fit the data using only Raman and quantum tunneling processes, and thus the temperature dependence of the relaxation times for 2 was fit using the following equation that includes Raman, Orbach and quantum tunneling contributions.

\[ \tau^{-1} = C T^n + z_0^{-1} \exp(-U_{eff}/k_B T) + \tau_{tunnel}^{-1} \]  
(Equation 1)

For data collected under zero applied field, the resulting fit parameters are \(n = 3.54, C = 0.00603 \text{ s}^{-1} \cdot \text{K}^{-n}, \tau_{tunnel} = 0.0427 \text{ s}, \)

\(\tau = 9.63 \times 10^{-12} \text{ s}, \) and \(U_{eff} = 336 \text{ cm}^{-1}\). Under a 1200 Oe dc field, \(n = 4.42\) and \(C = 2.23 \times 10^{-6} \text{ s}^{-1} \cdot \text{K}^{-n}\) while \(z_0\) and \(U_{eff}\) remained unchanged relative to the zero-field data. While the fitted relaxation barrier of 336 cm\(^{-1}\) agrees well with the energy of the first excited doublet determined by luminescence measurements (335 cm\(^{-1}\)) and reasonably well with ab initio calculations (282 cm\(^{-1}\)), other values of \(U_{eff}\) and \(z_0\) were also found to reproduce the evolution of relaxation times in the observed temperature range (Figure S25 and Table S13). Therefore, the lack of a clear linear regime in the relaxation data for 2 makes it impossible to definitively characterize the higher-temperature relaxation behavior.
out-of-phase susceptibility and, above 28 K, two overlapping peaks become resolved, with the slower of the corresponding processes persisting up to 50 K within the 1-1500 Hz frequency range. Thus, for \( T > 28 \) K, extracting magnetic relaxation times required use of a two-component Debye model (see Table S9), and the resulting Arrhenius plot for 1 exhibits one relaxation time below 28 K and two relaxation times above 28 K. In contrast to compound 2, a linear regime can clearly be observed for 1, indicating the presence of an Orbach relaxation process. To fit this complex ac data, Equation 1 was first used to obtain a set of parameters corresponding to the faster relaxation regime, resulting in values of \( n = 3.46, C = 9.42 \times 10^{-4} \text{ s}^{-1} \text{K}^{-n}, \tau_{\text{Orbach}} = 0.76 \text{ s}, \gamma = 1.48 \times 10^{-11} \text{ s}, \text{ and } U_0 = 432 \text{ cm}^{-1} \) (Figure 4, red lines). The slower regime was then independently fit with the same equation using the following parameters: \( n = 9, C = 2.02 \times 10^{-9} \text{ s}^{-1} \text{K}^{-9}, \tau_{\text{Orbach}} = 0.76 \text{ s}, \gamma = 2.82 \times 10^{-15} \text{ s}, \text{ and } U_0 = 528 \text{ cm}^{-1} \) (Figure 4, blue lines). The relaxation barrier of 432 cm\(^{-1}\) extracted for the fast regime is notably close to the energy of the second excited doublet determined by luminescence measurements (453 cm\(^{-1}\)) and \( ab \) initio calculations (477 cm\(^{-1}\)). Therefore, relaxation likely occurs by thermally-assisted quantum tunneling through the second excited doublet. This experimental observation indicates a highly axial first excited doublet with suppressed quantum tunneling, as supported by the \( ab \) initio calculations. For the slower relaxation regime, the relaxation barrier of 528 cm\(^{-1}\) extracted from the ac data is strikingly close to the position of the third excited doublet determined by luminescence measurements (527 cm\(^{-1}\)) and also agrees reasonably well with the value obtained from \( ab \) initio calculations (573 cm\(^{-1}\)). The assignment of this slowest process is made on the basis of the probability of a transition to \( |+13/2> \) state in 2, which is three times more probable than the \( |+11/2> \) transition to \( |+11/2> \) state and a phonon-assisted transition to \( |+11/2> \) state is three times more probable than the same transitions in 1 (Figures 6 and S28). Likely, this difference arises due to the more distorted coordination sphere of the Dy\(^{III}\) complex in 2. We thus ascribe the thermally-activated slow magnetic relaxation for 2 as occurring through the first excited state, in line with our experimental observation. In contrast, in compound 1 the probability of a transition becomes significant only for the \( |+11/2> \) state, and the calculation supports thermally-assisted quantum tunneling in the second excited doublet as the main mechanism for relaxation.

In conclusion, we have presented the first Dy\(^{III}\) complexes bearing a terminal fluoride ligand, and explored the influence of this highly electrostatic metal–ligand interaction on the electronic structure. From the correlations between high-resolution luminescence data, results from magnetometry measurements, and \( ab \) initio calculations,\(^{[16]}\) it is clear that such an architecture gives rise to a large crystal field splitting of the ground state and a pronounced axial magnetic anisotropy for the ground magnetic doublet, as well as for the first and second excited doublets for the more symmetrical complex in 1. These air-stable complexes further exhibit slow relaxation of the magnetization, while compound 1 appears to relax through a large, multilevel barrier.

Magnetic hysteresis was also observed in the magnetization versus field curves for both compounds, up to 7 and 4 K for 1 and 2, respectively (Figures 5 and S27). Both compounds exhibit waist-restricted hysteresis loops, as expected due to the observed contribution of quantum tunneling at low temperatures in the zero-field ac susceptibility data.

To better understand the origins of magnetic blocking in these compounds, the transition probabilities between different sub-states were extracted from the \( ab \) initio calculations, without taking into account phonon-driven mechanisms.\(^{[74, 14]}\) Of particular interest is the fact that distinct relaxation behaviors were observed for the two compounds, despite their very similar crystal field splittings. Examining the probability of a transition from the first excited \( |+13/2> \) state in 2, we find that both quantum tunneling to the \( |−13/2> \) state and a phonon-assisted transition to \( |−11/2> \) are three times more probable than the same transitions in 1 (Figures 6 and S28). Likely, this difference arises due to the more distorted coordination sphere of the Dy\(^{III}\) complex in 2. We thus ascribe the thermally-activated slow magnetic relaxation for 2 as occurring through the first excited state, in line with our experimental observation. In contrast, in compound 1 the probability of a transition becomes significant only for the \( |+11/2> \) state, and the calculation supports thermally-assisted quantum tunneling in the second excited doublet as the main mechanism for relaxation.

Figure 5. Hysteresis in the \( M/H \) curve for 1, collected at temperatures ranging from 2 to 7 K with a 10 mTs\(^{-1}\) sweep rate.

Figure 6. Calculated ground state splitting for 1 with the probability of transition between different sub-states, showing the most probable routes for magnetic relaxation in 1 (see SI for details).
Our continued efforts are focused on fully realizing the potential of these highly anisotropic units by minimizing competing fast relaxation pathways, through suppression of dipolar coupling, isotopic enrichment,[16] or the introduction of an exchange interaction.[17]
