ABSTRACT

Herein, we report on the theoretical-experimental analysis of the two photon absorption and circular dichroism spectra of 1-(2-pyridyl)-4-methoxy-carbo[6]helicene derivative (P6). The primary outcomes of our investigation on this particular helicene derivative with a donor-acceptor motif on one end led to two important conclusions: 1) The lengthening of the π-electron delocalization within the helical core of P6 predominantly increases the contribution of the magnetic dipole transition moment to the TPCD signal; 2) The electric quadrupole transition moment contribution to the TPCD signal is enhanced by the intramolecular charge transfer (ICT) produced by the donor-acceptor combination on one end of the molecule. In order to corroborate our results, we performed a comparative theoretical analysis of the effect of the energy gap and ICT on TPCD on a series of P6-like helicenes with different donor-acceptor combinations. Two-photon absorption (TPA) and two-photon circular dichroism (TPCD) spectra were obtained using the double L-scan technique over a broad spectral range (400-900 nm) using 90 fs pulses at a low repetition rate (2-50 Hz) produced by an amplified femtosecond system. The theoretical simulations were calculated using Time-Dependent Density Functional Theory (TD-DFT) at the CAM-B3LYP/6-311++G(d,p) level of theory.
INTRODUCTION

The interpretation of the high optical activity in helicenic systems and its combination with other properties like strong absorption and emission in the visible spectral range and redox activity\textsuperscript{1-3} has been the focus of investigation during the last twenty years. Chiral molecules such as helicenes are becoming more and more popular because of their direct application in asymmetric catalysis,\textsuperscript{4-5} chiroptical switches,\textsuperscript{6} enantioselective fluorescence detectors,\textsuperscript{7} circularly polarized emitters for chiral OLEDs,\textsuperscript{8-9} and nonlinear optical (NLO) devices.\textsuperscript{10-11}

Great efforts have been made in the development and application of two techniques, circular dichroism (CD) and optical rotatory dispersion (ORD).\textsuperscript{12} CD is known as electronic circular dichroism (ECD) when linked to transitions between electronic states and it is expressed as the difference between left (LCPL) and right (RCPL) circularly polarized light of one-photon absorption.\textsuperscript{13-14} Although, ECD has been the most common technique for the analysis of conformational and physical-chemistry properties of optically active molecular systems,\textsuperscript{12} it presents significant challenges for their study in the UV region.\textsuperscript{15} Among the most predominant are: absorption from buffers and solvents in the same spectral region, as well as scattering enhancement from heterogeneous samples. These could result in the hindrance of the ECD signal at shorter wavelengths.

In order to circumvent aforementioned shortcomings of ECD, scientist in the field have proposed multiple linear\textsuperscript{16-19} and non linear\textsuperscript{20-23} polarization dependent methods. The latter includes two-photon circular dichroism (TPCD),\textsuperscript{24} which is the nonlinear counterpart of ECD, i.e. the difference in two-photon absorption cross-sections obtained with LCPL and RCPL at a specific wavelength ($\Delta \delta^{\text{TPCD}}(\lambda) = \delta^{\text{TPA}}_L(\lambda) - \delta^{\text{TPA}}_R(\lambda)$).\textsuperscript{25-27} Since typical excitation wavelengths in TPA are approximately two folds longer (degenerate case) than in OPA, negligible absorption at the
excitation wavelength and minimization of scattering are observed.\textsuperscript{28-29} TPA is known for its intrinsic spatial resolution and penetration,\textsuperscript{29} as well as better background discrimination and reduced photodamage to living specimens.\textsuperscript{28} All these advantages combined with the characteristic sensitivity of TPCD to structural changes and accessibility to the far ultra violet (far-UV)\textsuperscript{30} make of this technique an excellent candidate for studying conformational and structural distortions of optically active chiral molecules in the far-UV.

The first experimental attempt to measure TPCD was made in 1995 by Richardson and co-workers, who used the fluorescence-detected two-photon circular dichroism (FD-TPCD) method.\textsuperscript{31} However, it was not until the advent of the double L-scan technique that full experimental TPCD spectra in optically active molecules were measured.\textsuperscript{32} Since then, TPCD became one of the best option for the structural study and conformational understanding of chiral molecules.

In the quest to increase the current understanding of the structure-property relationship of TPCD, we have been working on the theoretical-experimental analysis of the TPCD response in various molecular systems.\textsuperscript{24, 30, 33-37} With these investigations, we have nurtured our knowledge of TPCD in organic molecules. However, more systems need to be examined in order to fully explore this nonlinear optical property and its capability. In order to achieve this goal, herein, we present the theoretical-experimental analysis of the effect of pseudo-localized intramolecular charge transfer on the TPA and TPCD signal of a specific organic molecule with extended π-electron delocalization, helical chirality, and different donor-acceptor group combinations on one end. We first demonstrate that the lengthening of the π-electron delocalization within the helical core of \textbf{P6} due to the presence of the pyridine moiety, predominantly increases the contribution of the magnetic dipole transition moment to the TPCD signal. This is explained by the observed
decrease in the corresponding HOMO-LUMO energy gap and its direct correlation with the molecular angular momentum. Next, we show that the replacement of the pyridine moiety present in P6 by stronger electron withdrawing substituents (eWS) enhances the electron transfer towards eWS. This effect results in a higher electric quadrupole transition moment contribution to the TPCD signal.

**EXPERIMENTAL SECTION**

P-(+) and M-(-) enantiomers of 1-(2-pyridyl)-4-methoxy[6]helicene (P6) were synthesized according to a published procedure. Circular dichroism spectra (in M⁻¹ cm⁻¹) were measured on a Jasco J-815 Circular Dichroism Spectrometer (IFR140 facility - Université de Rennes 1) in dichloromethane and at concentrations around 5x10⁻⁵ M.

OPA measurements were carried out in a single-beam spectrophotometer (Agilent 8453 Diode Array UV-Vis) from 190 to 600 nm in a 0.1 cm quartz cuvette in solutions with a concentration range from 2.0x10⁻⁵ to 2.0x10⁻⁴ M in THF. ECD spectra were performed in a J-815 CD spectropolarimeter (Jasco Corp., Tokyo, Japan). Solutions were prepared at a concentration of 1.0x10⁻⁵ M in THF, at 25 °C, and in a 4 mm quartz cuvette. The ECD spectral region scanned ranged from 190 nm to 600 nm with a 1 nm step and a scan speed of 50 nm/min.

TPA and TPCD experiments were completed by using the Double L-scan technique in solutions with concentration of 8.7x10⁻² M in THF. Two-photon excitation was generated with a computer-controlled femtosecond optical parametric amplifier (OPerA Solo) pumped by an amplified laser system from COHERENT, Inc. The entire system is capable of generating 90 fs (FWHM) pulses over a wavelength range from 240 nm to 2.6 μm, and pulse energies of up to 350 μJ. Measurements were done at a repetition rate ranging from 2 to 50 Hz to avoid any contribution.
from cumulative effects. The pulse width was measured by a single-shot autocorrelator from COHERENT, Inc. and a frequency-resolved optical gaiting (FROG) from Swamp Optics, LLC.

**COMPUTATIONAL METHODS**

The molecular structure of $M(-)$ and $P(+)$-P6 and the other donor-acceptor helicenes (Figure 1) were optimized using Density Functional Theory (DFT), with the Coulomb attenuating method-Becke’s three-parameter exchange, Lee, Yang and Parr correlation (CAM-B3LYP) hybrid functional in combination with the 6-311++G(d,p) basis set, employing Gaussian 09. Solvent effects were taken into consideration through the polarizable continuum model (PCM).

![Figure 1. Chemical structures of $P(+)$-1-(2-pyridyl)-4-methoxy[6]helicene (P6) and eight donor-acceptor P6 derivatives.](image)

Then, we calculated the oscillator strengths ($f_{0f}$) and velocity rotatory strengths ($R_{0f}^{ECD}$) for the first 100 electronic excited states for P6 and all the donor-acceptor helicene derivatives.
employing Time-Dependent DFT (TD-DFT)\textsuperscript{39} at the CAM-B3LYP\textsuperscript{40} /6-311++G(d,p)\textsuperscript{41-42} level of theory. CAM-B3LYP was selected as XCF because it has been proven to be more reliable than B3LYP in the prediction of excited states of molecules with ICT. Solvent effects were included in the calculations by using PCM\textsuperscript{44} in Gaussian 09\textsuperscript{43}. The convoluted theoretical OPA and ECD spectra were obtained using Equations (1) and (2) with a Lorentzian shape and linewidth ($\Gamma$) of 0.28 eV (FWHM). OPA spectra are reported in molar absorptivity ($\varepsilon$),

$$
\varepsilon^{\text{OPA}}(\omega) \approx 1.05495 \times 10^3 \times \omega \sum_f g(\omega, \omega_{0f}, \Gamma) \frac{f_{0f}}{\omega_{0f}},
$$

(1)

where $\omega$ is the circular frequency of the incident light and $g(\omega, \omega_{0f}, \Gamma)$ is the line broadening function centered at $\omega = \omega_{0f}$.

ECD spectra were calculated from $R_0^{\text{ECD}}$, and they are reported in molar absorptivity difference ($\Delta \varepsilon$),

$$
\Delta \varepsilon^{\text{ECD}}(\omega) \approx 2.73719 \times 10^1 \times \omega \sum_f g(\omega, \omega_{0f}, \Gamma) R_0^{\text{ECD}},
$$

(2)

The units of OPA and ECD are mol\textsuperscript{-1}cm\textsuperscript{-1}, if the elements in equation (1) and (2) are in atomic units.

Finally, TPA probabilities ($\delta_{0f}^{\text{TPA}}(\omega_{0f})$) and TPCD rotatory strength ($R_0^{\text{TPCD}}(\omega_{0f})$) for P6 and all the eight theoretical donor-acceptor P6 derivatives were computed using TD-DFT\textsuperscript{39} in DALTON 2013.\textsuperscript{45} CAM-B3LYP\textsuperscript{40} hybrid functional was employed in combination with 6-311++G(d,p) basis set\textsuperscript{41-42} for the calculation of the first 60 electronic excited states for all the molecules. The number of excited states was selected based on the experimental spectral range (200 to 450 nm) covered by the measurements. No solvent effects were taken into account in the nonlinear calculations due to the high computational cost. The convoluted theoretical TPA and TPCD spectra were obtained by a normalized Lorentzian shape with a linewidth ($\Gamma$) of 0.2 eV.
(FWHM). The $R_{0f}^{TPCD}(\omega_{0f})$ were calculated from the electronic transitions employed in equations (3) and (4), where TPA spectra were simulated with,

$$\delta^{TPA}(\omega) \approx 8.35150 \times 10^{-4} \times \omega^2 \sum_f g(2\omega, \omega_{0f}, \Gamma)\delta_{0f}^{TPA}(\omega_{0f}),$$  \hspace{1cm} (3)

here $g(2\omega, \omega_{0f}, \Gamma)$ is the line broadening function and $\delta_{0f}^{TPA}$ is the orientationally averaged two-photon probability for the degenerate case.

TPCD spectra were computed from,

$$\Delta\delta^{TPCD}(\omega) \approx 4.87555 \times 10^{-5} \times \omega^2 \sum_f g(2\omega, \omega_{0f}, \Gamma)R_{0f}^{TPCD}(\omega_{0f}),$$  \hspace{1cm} (4)

TPA and TPCD spectra computed from (3) and (4) are reported in Göppert-Mayer (GM), which is equivalent to $10^{-50}$ cm$^4$ s mol$^{-1}$ photon$^{-1}$ when the elements of the equations are in atomic units.

In order to justify the use of the CAM-B3LYP hybrid functional for P6 we calculated the molecular orbitals involved in the most important electronic excitation on the red side of the theoretical ECD (#3) spectrum. The obvious ICT observed in Figure 2, makes the selection of CAM-B3LYP reliable for our analysis. Similar evidences have already been reported by Rizzo and co-workers in various molecular systems. 33, 37, 46-48
Figure 2. Molecular orbitals (MOs) involved in the 3rd electronic excited state of P6. The MOs were obtained from CAM-B3LYP/6-311++G(d,p) TD-DFT calculations in THF using PCM in Gaussian 09. The percent contribution of each single excitation ([HOMO-x] → [LUMO + y] to the excited state is indicated next to each arrow.

RESULTS AND DISCUSSION

In Figure 3, we show the experimental ECD and TPCD spectra for both enantiomers of P6, M(-) and P-(+)P6 in THF. From this Figure we can corroborate that TPCD is a sensitive technique for unequivocal enantiomeric identification. This is so, because one could say that the spectrum of one enantiomer is almost a specular image of the other, as expected. For this reason, the more extensive elucidation of the ECD and TPCD spectra of P6 will mainly focus on P-(+)P6, since similar arguments apply to M(-)P6.
**Figure 3.** Experimental a) TPCD and b) ECD spectra for $P-(+)-P6$ and $M-(-)-P6$ in THF and dichloromethane, respectively.

Then, the experimental OPA and ECD spectra (Figure 4.a and b) and the experimental TPA and TPCD (see Figure 4.c and d) spectra of $P6$ in THF solution are presented in Figure 4. This figure also displays the corresponding convoluted theoretical linear (OPA and ECD) and nonlinear (TPA and TPCD) spectra - linear and nonlinear excited states were computed using TD-DFT. For the linear calculations (100 electronic excited states), solvent effects were considered using PCM.
For the nonlinear theoretical spectra, the lowest 60 excited states were obtained without taking solvents effects into account due to high computational cost. In order to obtain a better overlapping between theoretical and experimental bands, the theoretical linear and nonlinear spectra were spectrally shifted by the amount reported in the caption of Figure 4. This is a common practice for theoretical-experimental works.24, 33-34, 36-37, 46, 49

Figure 4. Experimental (black solid and scattered line) and theoretical (green dotted line) of: a) UV-Vis, b) ECD, c) TPA, and d) TPCD spectra of P-(+)-P6. Colored symbols display the oscillator strength in the case of UV-Vis and ECD and TPA probabilities and rotatory strength in the case of TPA and TPCD, respectively. The OPA and ECD were calculated for the 100 lowest electronic excited states at the CAM-B3LYP/6-311++G(d,p) level of theory using Gaussian 09 in THF employing PCM. The theoretical linear spectra are only shown within the measurable spectral range (200-450 nm) with +10 nm spectral shift. \( \Gamma = 0.28 \) eV (FWHM) was used for OPA and ECD. The TPA and TPCD spectra were computed for the first 60 excited states at the CAM-B3LYP/6-311++G(d,p) level of theory in vacuo using Dalton 2013. The theoretical shift for the
non-linear spectra was +50 nm and the $\Gamma = 0.2$ eV (FWHM).

The first interesting observation to highlight from Figure 4 is the remarkable theoretical-experimental overlapping in all four spectra. The theoretical spectra extraordinarily reproduced the shape, position of the bands, and the fano-type shape profile of the experimental spectra. As mentioned before, the great performance of the chosen XCF is attributed to the presence of ICT in P6. The second important observation is the differences in TPA cross-sections between theoretical and experimental spectra, where the former is larger than the latter. This differences have been previously observed in other molecules$^{46,49}$ and are very hard to explain considering the fact that the measurements were performed in the femtosecond regime where excited state absorption is almost negligible.$^{50-51}$ Next, it is worth noting that the sign and relative intensities of the two main bands (290 and 260 nm) in TPCD were notably reproduced.

In order to gain more insight about the effects of a structural motif on the linear and nonlinear chiroptical properties of conjugated organic molecules with helical chirality, we embarked on a theoretical investigation of several molecular systems with different terminal donor-acceptor motifs on the helicene core of P6-like structures (see Figure 1). We performed calculations of OPA, ECD, TPA, and TPCD on four different moieties on position 1 and four different substituents in position 4 (see Figure 1). The substituents were selected based on their ability to affect the electron density of the helicene core. In order to perform a systematic selection of the corresponding substituents, we used the Hammet parameter ($\sigma$), which provides a qualitative (negative $\sigma$ for electron releasing and positive for electron withdrawing substituents) and quantifiable scale for the electron withdrawing and releasing strength of the groups (see Tables 1 and 2).$^{52-53}$

In Figure 5, we present the comparative plot of the OPA, ECD, TPA and TPCD theoretical spectra for all four different substituents for position 4, as well as the theoretical spectra for P6.

First, we decided to vary the substituent in position 4, keeping the substituent in position 1 as in P6 (see the combinations in Figure 1). The OPA and ECD signals are not strongly affected by the nature of the substituents in this position. In this figure, one can only observe an almost negligible increase in the amplitude and a red shift on the red side of the fano-type band of the ECD signal.
Figure 5. OPA, ECD, TPA, and TPCD theoretical spectra of all different substituents of position 4 including P6. OPA and ECD were obtained from the Lorentzian convolution ($\Gamma = 0.2$ eV FWHM) of the first 60 excited states of their optimized structures calculated at the CAM-B3LYP/6-311++G(d,p) level of theory in THF using PCM employing Gaussian 09. TPA and TPCD spectra of all optimized structures were obtained from the Lorentzian convolution ($\Gamma = 0.2$ eV (FWHM)) of the first 60 excited states. The nonlinear calculations were performed at CAM-B3LYP/6-311++G(d,p) level of theory in vacuo using Dalton 2013.

In TPA, two main bands are identified, the first at approximately 260 nm and the second at 200 nm. The intensity of the first band is similar in all five derivatives. However, the second band changes its intensity from 20 GM in H to 34 GM in NHCOCH$_3$. In the TPCD spectra, one can also notice that the first band is unaffected by the substitution in position 4. However, the apparent change in intensity observed in the second band of the -NHCOCH$_3$ derivative is attributed to the fusion of the double-peak band present in the other four molecules to produce an intense single-
peak band.

Next, we varied the substituent in position 1, keeping the moiety in position 4 as in P6 (see the combinations in Figure 1). In Figure 6, we present the OPA spectra of the four derivatives of the second series. Interesting to highlight is the small red shift (30 nm) experienced by the band centered at approximately 320 nm in -CN, -SO3H, and P6. Likewise in ECD, we see a similar shift in the same three derivatives. This interesting result reveals the extension of the conjugation length introduced by the pyridine moiety on the outside of the helicene core in P6, an effect not present in the other four derivatives.

Moving on to the TPA spectra, another interesting point to highlight, which is only observed in the two strongest electron withdrawing groups, is the presence of a strong band at approximately 180 nm, which TPA cross section varies from 28 GM for P6 to 48 GM for the -SO3H substituted. This result is supported by previous theoretical results published by Yan and co-workers (2012), where they demonstrated that conjugated molecules with a push-pull motif present an enhanced TPA cross section as a result of the intramolecular charge transfer, which increases the electric dipole transition moments between the ground and excited states.54 To corroborate this finding, we calculated the resultant electric dipole transition moment for the 3\textsuperscript{rd} electronic excited state (see Table 3) - same electronic excited state selected previously for corroborating the charge transfer character of P6. As expected, one can clearly see that, at least for this electronic excited state, the resultant electric dipole transition moment is larger for CN and SO3H than for P6.

Figure 6. OPA, ECD, TPA and TPCD theoretical spectra of all five different substituents. OPA and ECD spectra were obtained from the Lorentzian convolution ($\Gamma = 0.2$ eV FWHM) of the first 100 electronic excited states of the optimized structures of all different five substituents at the CAM-B3LYP/6-311++G(d,p) level of theory in THF using PCM and employing Gaussian 09. TPA and TPCD spectra of the optimized structures were calculated from the Lorentzian convolution ($\Gamma = 0.2$ eV FWHM) for the first 60 electronic excited states. TPA and TPCD
calculations were performed at the CAM-B3LYP/6-311++G(d,p) level of theory in vacuo using
Dalton 2013.

The molecular orbitals for the most important single excitations contributing to the 3rd excited
state of SO$_3$H presented in Figure 7, evidently expose the greater ICT character of -SO$_3$H when
compared to P6 (see Figure 3). On the one hand, in the HOMO and HOMO-1 energy levels, one
can see that the electrons are mainly delocalized in the aromatic ring of the molecular system. In
the LUMO and LUMO+1 energy levels, the electron density goes more towards the -SO$_3$H group
due to its higher electron withdrawing character. Consequently, the ICT effect is more evident in
the helicene with the -SO$_3$H substituent than in P6.

![Figure 7](image)

*Figure 7.* Molecular orbitals (MOs) involved in the 3rd electronic excited state of SO$_3$H. The MOs
were obtained from CAM-B3LYP/6-311++G(d,p) TD-DFT calculations in THF using PCM in
Gaussian 09. The percent contribution of each single excitation ([HOMO-x] → [LUMO + y]) to
the excited state is indicated next to each arrow.
Finally, we analyzed the TPCD spectra of all five substituents in position 1 (Figure 6). Once again, the positive band that appears towards the red side of the spectra seems to be unaffected by the donor-acceptor combination of the substituents. However, the band located at approximately 200 nm changed in shape and sign. In the case of P6 and -Cl, one can notice a negative double-peak band in this region. For -CN and -SO₃H, this band emerges as a negative single-peak band at 210 nm that turns into a positive band at 180 nm. Knowing that TPCD signal directly depends on the different contributions from the electric quadrupole transition moment (accounted for on the molecular parameter B₂) and the magnetic dipole transition moment (accounted for on the molecular parameters B₁ and B₃), a comparison of the sum of the absolute values of molecular parameters B₁+B₃ and B₂ for all five substituents in position 1 and 4 is presented in Figure 8.

Figure 8. Comparative bar graph of a)  \( \Sigma |B₁+B₃| \) and b)  \( \Sigma |B₂| \)  for all substituents of a) position 4 and b) position 1.
In this Figure, one can identify three main groups (identify with different backgrounds patterns and colors): the blue squared pattern indicates that these substituents act as electron releasing groups based on their negative Hammet constant, the green diagonal cross pattern designates the electron withdrawing groups with positive Hammet constants, and the grey dotted area corresponds to -H, which was used as a reference (see tables 1 and 2).

The analysis of the different highlighted regions in the Figure shows a clear trend on the contribution of the magnetic dipole transition moment ($\Sigma |B_1+B_3|$) to the TPCD spectra with respect to their donor-acceptor character. It can be observed that $\Sigma |B_1+B_3|$ is always greater for $\text{P6}$ than the $\text{P6}$-like molecules with different substituents. However, the contribution of the electric quadrupole transition moment ($\Sigma |B_2|$) to the TPCD spectra is larger for $\text{P6}$ on the electron releasing moieties and larger for $-\text{CN}$ on the electron withdrawing series. In order to explain these trends, we calculated the HOMO and LUMO energies for each $\text{P6}$-like derivative, $\text{P6}$ included, employing DFT. The calculated energies, as well as the energy gaps of these molecules are presented in Figure 9.

From Figure 9.a, which compares the effect of the strength of donor groups in position 4, one can deduce that as the electron releasing character increases, so does the LUMO energy of the helicene derivatives. This is corroborated by the change in tendency observed in a weak electron withdrawing substituent such as $-\text{CH}_3$ (the LUMO energy increases again, Figure 9.a). Now, in Figure 9.b, which assesses the effect of the strength of attractor groups in position 1, one can observe an overall decrease of the LUMO energy as the electron withdrawing character increases.

After completing the examination of the effect of contributions of $\Sigma |B_1+B_3|$ and $\Sigma |B_2|$ to the TPCD spectra of both series of $\text{P6}$-like derivatives (Figure 8), and the effect of energy gap (HOMO-LUMO) in the same two series, we proceeded to evaluate the existing correlations.
between the two. Through this analysis, an inverse dependency between the magnetic dipole transition moment contribution to the TPCD and the energy gap was noticed, i.e. the lower the energy gap the higher $\sum |B_1 + B_3|$. This can be explained based on previous works reporting that a decrease in energy gap causes an increase in the angular momentum.\(^{55}\) Therefore, because the angular momentum is directly correlated with the magnetic moment, an increase in the angular momentum results in a higher magnetic dipole transition moment.\(^{56}\)

![Figure 9. Calculated HOMO energies, LUMO energies, and energy gaps of all the donor-acceptor combinations substituents for a) position 4 and b) position 1.](image)

In order to corroborate the established correlation between $\sum |B_1 + B_3|$ and $\sum |B_2|$ and the donor-acceptor combination in P6 derivatives, we calculated the frontier molecular orbitals (FMOs) of all nine molecules (see Figure 10). The FMOs were obtained using DFT. In Figure 10.a, one can observe, in most of the derivatives, that the electron density over the substituents on one end of the molecule is higher in the HOMO than in the LUMO. This reveals the strong electron withdrawing character of the helical core in P6-like derivatives with different electron donating moieties. On the contrary, the FMOs presented in Figure 10.b show a strong ICT between the two moieties with push-pull arrangement on one end on the derivatives rather than through the helicene
core. In summary, the presence of strong withdrawing substituents such as –CN and –SO₃H in position 1 tend to originate a larger contribution to TPCD through the electric quadrupole transition moment, while the pure existence of an aromatic ring like pyridine in P6 that can extend the length of the π–electron delocalization beyond the helical core creates a stronger contribution to TPCD through the magnetic dipole transition moment.

**Figure 10.** The Frontier Molecular Orbitals (FMOs) of all substituents of a) position 4 and b) position 1. The molecular orbitals were obtained using DFT at the CAM-B3LYP/6-311++G(d,p) level of theory in THF using PCM and employing Gaussian 09.
CONCLUSIONS

It was observed that one-photon signals are not strongly affected by the nature of the substituents. However, it was demonstrated that TPA and more specifically TPCD are more sensitivity to structural changes. Furthermore, the analysis of the effect of localized ICT on one end of helicene derivatives on the contribution transition moments of TPA and TPCD revealed that: a) the lengthening of the $\pi$-electron delocalization, within the helical core of P6, predominantly increases the contribution of the magnetic dipole transition moment to the TPCD signal, and b) the electric quadrupole transition moment contribution to the TPCD signal is enhanced by the localized ICT produced by the donor-acceptor combination on one end of the molecule. These two effects were certified by the analysis of FMOs in all the nine derivatives.

ACKNOWLEDGEMENTS

Jeanne Crassous thanks the Ministère de l'Education Nationale, de la Recherche et de la Technologie and the Centre National de la Recherche Scientifique (CNRS). This work has been partially supported by the National Science Foundation through Grant Number NSF/ARRA-0840431 and NSF/DBI-1422826. The extended computing time provided by STOKES ARCC/UCF is gratefully acknowledged.
