1 **Abstract:**

2 Purpose: Radioembolization (RE) is a promising treatment option for biliary tract cancers (BTC). We
3 report here the largest series to date using this treatment modality.

4 Methods: We retrospectively studied data from 64 patients treated outside prospective clinical trial
5 at our institution. We studied baseline characteristics as potential prognostic factors. We studied
6 dose delivered to the tumor as predictive factors of outcomes in patients not receiving concomitant
7 chemotherapy.

8 Results: The Progression-Free Survival and Overall Survival (OS) survival were 7.6 months [95%
9 Confidence Interval (CI): 4.6-10.6] and 16.4 months [95% CI: 7.8-25.0] in the whole cohort. The
10 factors independently associated with OS in multivariable analysis were the primary localization of
11 ICC (HR=0.27, 95% CI: 0.11-0.68, p=0.005) and a PS>0 (HR=2.21, 95% CI: 1.11-4.38, p=0.024). During
12 follow-up, 12 patients (19%) underwent surgery following downstaging, with a median OS was 51.9
13 months. In patients not treated with concomitant chemotherapy (n=31), OS was significantly higher
14 in patients with a dose delivered to the tumor 260Gy or higher than in patients with a dose delivered
15 to the tumor lower than 260Gy (median 28.2 vs 11.4 months, log-rank p=0.019).

16 Conclusion: Our results confirm that RE is a promising treatment modality in BTC. A high proportion
17 of patients could be downstaged to surgery, with promising long term survival. Dose delivered to the
18 tumor correlated with clinical outcomes when chemotherapy was not used concomitantly.

19

20 Keywords: radioembolization, dosimetry, biliary tract cancer, 90Y, intrahepatic cholangiocarcinoma

1 **Introduction**

2 Intrahepatic cholangiocarcinoma (ICC) has a rising incidence in Western countries [1,2]. Other biliary
3 tract cancers (BTC) (hilar, distal cholangiocarcinomas and gall-bladder adenocarcinoma) have a high
4 propensity to metastasize to the liver. In advanced BTC, doublet chemotherapy with cisplatin and
5 gemcitabine became the standard treatment after the results of the ABC-02 study (a phase 3 study
6 showing the superiority of the cisplatin-gemcitabine combination over gemcitabine monotherapy)
7 and a subsequent meta-analysis [3–5].

8 ⁹⁰Y-microspheres radioembolization (RE), also known as selective internal radiation therapy, is
9 applied as a loco-regional treatment for malignant liver disease. Radiolabeled microspheres are
10 administered via the hepatic arteries, delivering a local radiation dose when reaching the tumor
11 vasculature. Multiple single-center series reported results of RE in BTC [6–17], however the largest
12 published to date included only 46 patients [11]. There is still considerable uncertainty about
13 potential prognostic factors and about the potential preferred population in which this treatment
14 should be applied [15,18]. Cucchetti et al suggested that mass-forming and first-line patients had the
15 best prognosis when comparing the results obtained across the different series available, however
16 this hypothesis was not tested in other cohorts [18]. We previously suggested that in first-line
17 patients, concomitant chemotherapy might provide additional benefit [8]. In contrast to what was
18 shown in Hepatocellular Carcinoma [19,20], in a previous analysis limited to first-line patients treated
19 with concomitant chemotherapy, we did not find a threshold dose to predict response to the
20 treatment, as almost all of the patients were responders with a lowest tumoral dose eliciting
21 response being 158Gy [21]. The present study reports our experience with RE in non resectable BTC
22 whatever the treatment line, and try to address potential predictive factors for survival or toxicity, in
23 order to better select ideal candidates for the treatment. We also pursued our work on dosimetry
24 focusing on the population not previously studied, namely the population without concomitant
25 chemotherapy.

1 **Material and methods**

2 Patients

3 We retrospectively analyzed data from patients treated at our institution with RE for unresectable
4 BTC (mostly ICC, but also extrahepatic BTC with metastases to the liver). Main inclusion criteria for RE
5 were histologically-proven BTC, with no or limited extrahepatic disease, involvement of 50% or less
6 of the liver volume by the tumor, adequate liver function (no cirrhosis or Child-Pugh class A cirrhosis,
7 with bilirubin level ≤ 35 $\mu\text{mol/L}$; we extrapolated Child Pugh score to patients without cirrhosis to
8 assess liver function), without elevated pulmonary shunt (with a lung dose higher than 30 Gy), and
9 performance status of 2 or lower. Exclusion criteria were the lack of follow-up available after RE
10 (patient gone to other centers without further information following RE). All patients were discussed
11 during a multidisciplinary team meeting specialized in liver malignancies including hepato-biliary
12 surgeons and radiologists, and their disease were judged unresectable. We included all consecutive
13 patients meeting inclusion criteria, but excluded patients enrolled in prospective clinical trials with
14 RE.

15 As previously described [8], we defined concomitant chemotherapy as the administration of
16 chemotherapy starting at a maximum of 3 months before RE, without any radiologic assessment of
17 response before RE. When chemotherapy was started 3 months or more before RE, and/or when
18 radiologic evaluation was performed before RE, we used the term induction chemotherapy [8].

19 Treatment received

20 The RE therapeutic procedure was performed as previously described [22]. The aim of the diagnostic
21 angiography was to define the best catheter position for right, left, or segmental treatment in order
22 to target the lesion. Percentage of pulmonary shunting and absence of digestive uptake were
23 assessed after $^{99\text{m}}\text{Tc}$ macroaggregated albumin was injected selectively in the hepatic artery
24 (185MBq). Planar and SPECT/CT acquisitions were performed. SPECT/CT acquisitions were conducted
25 using the following parameters: window $140 \pm 7.5\text{KeV}$; 32 projections; 180° ; $128 * 128$;

1 30s/projection (Symbia T2 gantry, Siemens). The data was reconstructed using an iterative method
2 (OSEM, 5 iterations, 8 subsets) with CT based attenuation correction and scatter corrections.
3 Radioembolization was performed 8 to 15 days later at a second angiography, using glass
4 microspheres. We performed only lobar treatment, one in case of unilobar, two in case of bilobar
5 disease, but some patients with anatomical variants could have 3 treatments. Activity administrated
6 was calculated with the aim of administering a dose between 80 and 150 Gy to the targeted liver
7 volume without exceeding a cumulative dose of 30 Gy to the lungs; however, in case of segmental or
8 bisegmental injection, dose to the segment could be higher than 150 Gy as previously described [19].
9 Segmentation (targeted liver and tumor) was performed on SPECT/CT data and not on the
10 angiographic and CT data usually used, as previously described [19, 21, 23]. The doses in the selected
11 volume of interest (VOIs), i.e., tumor, targeted liver, and healthy targeted liver, were calculated using
12 the classic medical internal radiation dose (MIRD) formula, given below:

13

$$14 \quad D_{VOI} \text{ (Gy)} = A_{VOI} \text{ (GBq)} \times 50 / W_{VOI} \text{ (kg)}$$

15

16 where D_{VOI} = mean dose in the VOI; A_{VOI} = total activity in the VOI; W_{VOI} = weight of the VOI with W =
17 volume of the VOI x 1.03. The Volumetric Analysis software (Syngo workstation, Siemens) was used
18 for the dosimetric evaluation

19

20 Four different chemotherapy regimens were administered, as follows: (1) the modified LV5FU2-
21 cisplatin regimen consisted in cisplatin at 50 mg/m² on day 1, 5FU bolus at 400 mg/m² on day 1, and
22 5FU continuous infusion at 2400 mg/m² upon 46 hours, cycles repeated every 2 weeks; (2) the
23 GEMOX regimen consisted in gemcitabine 1000 mg/m² on day 1 and oxaliplatin 100mg/m² either on
24 day 1 or 2, cycles repeated every 2 weeks; (3) the gemcitabine cisplatin regimen consisted in cisplatin
25 25 mg/m² on day 1 and 8 and gemcitabine 1000 mg/m² on day 1 and 8, cycles repeated every 3
26 weeks or (4) the gemcitabine regimen consisting in gemcitabine 1250 mg/m² on day 1, 8 and 15

1 repeated every 4 weeks. When patients received concomitantly gemcitabine and RE, the dose of
2 gemcitabine was reduced to 300mg/m² for the cycles preceding and after RE, by analogy to the
3 recommended dose for concomitant chemoradiotherapy in pancreatic cancer [24]. The
4 chemotherapy regimen varied across time according to evolution of standards of treatment,
5 according to patients' characteristics and according to some clinicians' preferences when patients
6 were coming from other institutions. Concomitant chemotherapy was administered on the day
7 before or after RE, but not on the same day. A line of chemotherapy is defined by a regimen.

8 Evaluation

9 Toxicity was retrospectively graded using NCI-CTCAE v4. We defined hepatic toxicity as the
10 occurrence or at least one grade worsening of ascites, bilirubin, or encephalopathy, even if these
11 toxicities were reversible. We considered acute hepatic toxicity if these toxicities occurred during the
12 first 3 months following RE, and total hepatic dysfunction whenever these toxicities occurred. We
13 assessed whether hepatic toxicity occurred after intra-hepatic progression of the disease, or if no
14 hepatic progression explained the hepatic dysfunction.

15 Response was prospectively evaluated by CT scan 6 to 8 weeks after RE, then every 2 to 3 months,
16 using RECIST 1.1 and Choi criteria, as we previously showed that Choi criteria might better predict
17 survival in this context [25,26].

18 Each analysis was performed with the use of a 2-sided α level of 0.05 by using the SPSS software v21.
19 The χ^2 or the Fisher tests was used for frequency comparisons. Survival data were analyzed with the
20 Kaplan-Meier method, log-rank test, and Cox regression model. Overall Survival (OS) was the time
21 between first RE and death, Progression-Free Survival (PFS) was the time between first RE and either
22 death or progression according to RECIST 1.1. Survival was not censored at the time of surgery.

23

24

1 **Results**

2 Between August 2010 and October 2016, 64 patients were treated by RE at our institution. Baseline
3 characteristics of the patients are reported in Table 1. The treatment applied is summarized in Table
4 2.

5 Median follow-up was 37.5 months. During follow-up, 45 patients (70%) experienced progression,
6 and 43 patients (67%) died. Following RE, in the 62 patients evaluable for response, best responses
7 according to RECIST were Partial Response in 9 (15%), Stable Disease in 38 (61%) and Progressive
8 Disease in 15 (24%). According to Choi criteria, it was Partial Response in 44 (71%), Stable Disease in
9 5 (8%) and Progressive Disease in 13 (21%). Patients experiencing RECIST progression had worse OS
10 (median 7.5 months), but there was no difference in OS between patients with RECIST Stable Disease
11 (median 28.2 months) and patients with RECIST Partial Response (median 21.5 months). In contrast,
12 Choi evaluation was able to distinguish between patients with Progressive Disease (median 7.5
13 months), patients with Stable Disease (median 19.1 months) and patients with Partial Response
14 (median 28.2 months) ($p<0.001$).

15 Median PFS for the whole cohort was 7.6 months [95% Confidence Interval (CI): 4.6-10.6] (Figure 1A).
16 Median PFS was longer for ICC patients than for other BTC, with a median of 9.1 months and 4.9
17 months respectively ($p=0.009$). No other parameter was associated with differences in PFS. PFS was
18 9.5 months [95% CI: 7.2-11.9] when RE was included in the first line of treatment vs 5.7 months when
19 it was used as further line, but the difference was not statistically significant ($p=0.49$). Progression
20 was seen in the treated lesion in 13 patients (20%), in the liver in 32 patients (50%) and outside the
21 liver in 32 (50%). All patients with progression in the treated liver had concomitant progression in
22 both the liver and outside the liver.

23 Median OS for the whole cohort was 16.4 months [95% CI: 7.8-25.0] (Figure 1B). There was a worse
24 survival in patients who had previous biliary stenting (median of 5.5 vs 19.1 months, $p=0.023$), in
25 patients with a primary location different from ICC (median of 5.5 vs 19.1 months, $p=0.009$) in

1 patients with a PS>0 vs PS=0 (median of 9.6 months vs 31.4 months, p=0.040) and in patients with a
2 tumor progressive after first-line chemotherapy (median of 7.5 vs 20.0 months, p=0.019). No other
3 parameter was associated with significant difference in OS. Regarding patients with biliary stent, 3
4 out of 4 (75%) died within 6 months due to hepatic failure without intra-hepatic progression, and one
5 died at 7 months due to multifocal extra hepatic progression. There was a trend toward a worse OS
6 when RE was used in later lines of treatment, with a median OS of 19.9 months when RE was
7 included in the first line, 11.4 months in the second line and 7.5 months in the third line and more
8 (p=0.10). PFS and OS median in different sub-groups are presented in Table 3.

9 During follow-up, 12 patients (19%) underwent surgery following downstaging. R0-surgery was
10 obtained in 8 patients (66%). Major hepatectomy were performed in all cases: two patients
11 underwent right lobectomy, three patients underwent left hepatectomy and 7 patients underwent
12 right hepatectomy (in 4 cases, extended to segment 1). Within 3 months post surgery, 9 patients
13 (75%) experienced complication; 3 presented pleural effusion, one developed ascites, 4 had hepatic
14 dysfunction and one presented a stroke. 3 patients (25%) experienced complication of grade 3 or
15 more. Among these 3 patients, two died: one had a massive stroke on postoperative day 9, one
16 developed a severe liver failure due to thrombosis of both the hepatic artery and portal vein.
17 Downstaging to surgery was more frequent in patients treated with RE as part of their first line
18 (10/36 patients, 28%) and in patients treated with concomitant chemotherapy (10/33 patients, 30%).
19 Median OS was 51.9 months [95% CI: 0.0-113.4] for patients who underwent a surgical resection vs
20 15.0 [95% CI: 5.3-25.6] for patients who did not (p=0.024, figure 2).

21 Toxicities during the first 3 months following RE (and in some case concomitant chemotherapy) were
22 reported in Table 4. Toxicity was absent in 25 (39%) patients. Some form of hepatic dysfunction was
23 seen in 26 (41%) patients during the follow-up. These hepatic dysfunctions occurred at a median of
24 7.2 months after RE (range: 1- 35 months), and occurred after intra-hepatic progression in 17 (74%),
25 after major hepatic surgery in 4 (6%), and with no specific associated factor, and thus considered

1 related to RE in 5 (22% of patients with hepatic dysfunction, 8% of the whole cohort). Three out of 5
2 have biliary stent. Hepatic dysfunction was seen more frequently in patients with bilobar disease
3 (17/36, 47%), than in patients with unilobar disease (6/28, 21%) ($p=0.033$), in patients with multifocal
4 disease (20/46, 44%) than in patients with unifocal disease (3/18, 17%) ($p=0.044$), and was also seen
5 in 6/12 (50%) cirrhotic patients vs 17/52 (33%) non-cirrhotic patients, albeit this difference was not
6 statistically significant ($p=0.26$). Hepatic dysfunction was associated with worse OS, with a median OS
7 of 10.0 months in case of dysfunction vs 33.8 months in the absence of dysfunction ($p=0.010$).

8 We then developed a prognostic model for OS. When entering only baseline characteristics
9 significantly associated with OS in univariable analysis, the factors independently associated with OS
10 in multivariable analysis were the primary localization of ICC (HR=0.27, 95% CI: 0.11-0.68, $p=0.005$), a
11 PS>0 (HR=2.21, 95% CI: 1.11-4.38, $p=0.024$). When considering also variables available after
12 treatment (response criteria and hepatic dysfunction), factor associated with OS were the primary
13 localization of ICC (HR=0.10, 95% CI: 0.03-0.31, $p<0.001$), a PS>1 (HR=3.16, 95% CI: 1.42-7.01,
14 $p=0.005$) and Choi response (HR=3.22, 95% CI: 1.88-5.53, $p<0.001$), but not RECIST response or
15 hepatic dysfunction.

16 We then focused on the ICC population. Median OS and PFS for patients with ICC was respectively
17 19.1 months [95% CI: 9.6-28.6] and 9.1 months [95% CI: 6.5-11.6]. In univariable analysis, PS>0 was
18 borderline significant $p=0,059$ (HR=1,970, 95% CI: 0.97-3.89). No parameter was significantly
19 associated with OS, due to limited power.

20 We finally studied dose delivered to the tumor as a predictor of clinical outcomes. Our previous work
21 focusing on patients treated in first-line with concomitant chemotherapy, we focused here on the
22 population not previously studied, namely the population without concomitant chemotherapy,
23 whatever the line of treatment ($n=31$). The dose delivered to the tumor did not correlate with RECIST
24 response, with a median of 263Gy in patients with RECIST objective response vs 269Gy in patients
25 without RECIST objective response ($p=1.00$); however, the dose delivered to the tumor differed with

1 Choi response, with a median of 280Gy in patients with Choi objective response vs 227Gy in patients
2 without Choi objective response ($p=0.050$, Figure 3A). We defined by Receiver Operating Curve
3 analysis the optimal threshold for dose delivered to the tumor as 260Gy as a predictor of Choi
4 objective response. Using this threshold, in the 29 patients evaluable for Choi response, 14/16 (88%)
5 treated with 260Gy or higher had objective response vs 5/13 (39%) treated with lower than 260Gy
6 ($p=0.016$, Figure 3B). Overall survival was significantly higher in patients with a dose delivered to the
7 tumor 260Gy or higher than in patients with a dose delivered to the tumor lower than 260Gy
8 (median 28.2 vs 11.4 months, log-rank $p=0.019$, HR=0.35, 95% CI: 0.14-0.87, $p=0.024$, Figure 3C). For
9 the ICC subgroup, OS was also significantly higher in patients with a dose delivered to the tumor
10 260Gy or higher than in patients with a dose delivered to the tumor lower than 260Gy (median 28.2
11 vs 11.4 months, log-rank $p=0.018$, HR=0.33, 95% CI: 0.12-0.86, $p=0.024$).

12

1 **Discussion**

2 This series is the largest series published to date reporting results of RE in BTC, and has also a long
3 median follow-up >3 years. This series confirms the promising results of RE in this context, with a
4 median OS of 16.4 months overall and 19.9 months in the first-line setting, comparing favorably with
5 results achieved with chemotherapy alone. Important new results are also the identification of
6 potential prognostic factors, the evidence of a high proportion of patients downstaged to surgery,
7 and the evidence of a correlation between dose delivered to the tumor and the response and OS.

8 Regarding the prognostic factors, our study might help to suggest the optimal population which
9 should be the focus of future studies. The multivariable analysis suggests that ICC are a more
10 favorable setting than other BTC with liver involvement, and finds that the main other prognostic
11 factor was PS. Multifocality of the disease and presence of extrahepatic spread did not seem to be
12 associated with OS, however we clearly selected patients with no major liver involvement (<50%) and
13 with limited extra-hepatic spread (mainly limited lymph nodes or small lung lesions). Moreover, we
14 did not find that infiltrative type was significantly associated with worse OS, but this may be related
15 to the low power of the study. Infiltrative type is also quite subjective, and might be difficult to
16 reproduce. We did not show significant difference in PFS or OS between lines of therapies, despite
17 some clear numerical differences (median OS of 19.9 months in first line, 11.4 months in second line
18 and 7.5 months in later lines).

19 RE was applied in this series in different clinical settings, ranging from first-line with one single but
20 unresectable lesion to third-line with multifocal spread. Our results suggest that application in the
21 first-line setting might be the best one for 2 main reasons. First, we found a better OS in the first-line
22 setting, even if it did not reached statistical significance. Second, and more importantly, the use in
23 first-line setting was associated with a high proportion of downstaging to surgery (28%), with an
24 impressive achieved median OS of more than 4 years in these operated patients, similar in this
25 initially unresectable population to what is seen in operable patients treated with adjuvant

1 chemotherapy in recent clinical trials [27,28]. We previously described surgical possibilities following
2 RE [8,29]. This high rate of downstaging to surgery and long survival might suggest that RE could be a
3 promising option in neoadjuvant strategies in unresectable but pauci-focal disease and also in
4 borderline-resectable cases, as R1- or resection with margin <5mm were shown to be prognostic in
5 ICC [30,31]. Additionally, a single-center study previously showed similar results in patients treated
6 with intra-arterial therapies than with surgery for ICC limited to the liver, suggesting that upfront
7 surgery might not be the only loco-regional treatment option [32]. However, our results suggest that
8 surgery following RE improved the results of RE alone, in patients that can be downstaged. This
9 should be further studied.

10 Toxicities were as expected with RE and chemotherapy, and mostly of low grade. We did see hepatic
11 dysfunctions, some occurring late after treatment, but in most cases it was associated with intra-
12 hepatic progression, and probably more related to the disease than the treatment. Liver dysfunction
13 in the absence of progression was seen in only 8% of the patients. However, it is important to note
14 the higher incidence of hepatic dysfunction in patients with multifocal disease (44%) in patients with
15 cirrhosis (50%), and in patients with biliary stent (3 out of 4): these patients are also at higher risk for
16 hepatic dysfunction in case of progressive disease.

17 We showed that a dose delivered to the tumor of 260Gy was predictive of outcomes in terms of Choi
18 response and OS. This differed from our previous results regarding EASL response in patients treated
19 in first-line with concomitant chemotherapy [21]. At least 2 difference between both studies might
20 explain the discrepancy with our previous work: first, concomitant chemotherapy is likely to decrease
21 the threshold for response, as we previously showed synergy between chemotherapy and ⁹⁰Y in
22 cholangiocarcinoma cell lines [33]. Indeed, in our previous work we were able to see responses with
23 doses as low as 158Gy in case of concomitant chemotherapy, suggesting very high sensitivity to
24 radiation in this setting. Second, we used here Choi response criteria, which we previously showed to
25 be better to evaluate response than RECIST criteria in patients treated with RE for ICC [26]. While

1 other have suggested EASL or mRECIST to be feasible in ICC, it might be less reproducible than Choi in
2 ICC, due to the peripheral and late pattern of enhancement, differing from Hepatocellular carcinoma
3 [10]. Finally, our results here are in lines with accumulating evidence of the importance of dosimetry
4 in RE [34].

5 Our study has some limitations. This is a single retrospective institution experience, thereby making
6 definitive recommendations difficult. Second, due to the relative rarity of unresectable biliary tract
7 cancer, our population is heterogeneous. This heterogeneity includes both patients' characteristics
8 (primary localization of BTC, size of tumor, presence of extra hepatic disease) and modality of
9 treatment (line of chemotherapy, induction or concomitant chemotherapy, surgical intervention).

10 In conclusion, this large series confirms the promising activity of RE in ICC. Prospective studies are
11 being carried on. We recently reported the promising results of MISPEHC, a multicentric phase 2
12 study of combination of RE and chemotherapy in first-line [35], and are awaiting further follow-up for
13 future publication of the results. Another study is comparing RE with transarterial
14 chemoembolization [36]. The SIRCCA phase 3 trial (clinicaltrials.gov identifier NCT02807181) is
15 currently randomizing patients with non-resectable ICC to either chemotherapy alone or RE followed
16 by chemotherapy. This study will have sufficient power to clearly demonstrate the role of RE in
17 advanced disease. Downstaging strategies in borderline cases should also be considered in future
18 studies, as well as proper consideration of dosimetry.

1 **Tables:**

2 Table 1: Baseline characteristics of the patients

	Whole cohort (n=64)
Gender	Male: 37 (58%) / Female: 27 (42%)
Performance Status	0: 33 (52%) 1: 24 (38%) 2: 1 (2%) Unknown: 6 (9%)
Primary tumor location	Intrahepatic: 57 (89%) Hilar: 6 (9%) Extra hepatic: 1 (2%)
Extra hepatic metastases	10 (16%)
Multifocal (>1 lesion) liver disease	46 (72%)
Bilobar liver disease	36 (56%)
Maximal diameter of the largest lesion, mm median (range)	77 (14-182)
Portal vein (main or branch) thrombosis	11 (17%)
Infiltrative tumor	30 (47%)
CA19.9, median UI/L (range) (n=58 with available data)	36 (0-5149)
Underlying cirrhosis	12 (19%)
Child score (calculated for cirrhotic and non-cirrhotic patients)	5: 57 (89%) 6: 7 (11%)
Albumin, g/L median (range)	40 (19-48)
Total Bilirubin, $\mu\text{mol/L}$ median (range)	11.7 (2.1-41.9)

Biliary stent	4 (6%)
Previous liver surgery	15 (23%)
Previous line of chemotherapy	0: 36 (56%) 1: 23 (36%) >1: 4 (8%)

1 Table 3: median PFS and OS in different subgroups

Parameter		Median PFS	p	Median OS	p
Whole cohort		7.6		16.4	
Chemotherapy during the line of RE	No	6.7	0.90	11.4	0.37
	Induction	3.5		10.1	
	Concomitant	9.5		19.9	
Line of treatment	1	9.5	0.38	19.9	0.10
	2	6.0		11.4	
	>2	5.5		7.5	
Cirrhosis	No	6.2	0.90	16.4	0.47
	Yes	10.1		11.4	
Primary Site	Intrahepatic	9.1	0.009	19.1	0.009
	Other	4.9		5.5	
Extrahepatic spread	No	7.7	0.25	15.0	0.82
	Yes	5.6		21.5	
Biliary Stent	No	8.0	0.064	19.1	0.023
	Yes	4.8		5.5	
Multifocal Disease	No	9.5	0.15	11.4	0.34
	Yes	6.0		16.4	
Bilobar Disease	No	8.9	0.16	11.4	0.96
	Yes	6.2		20.0	
Portal Vein Thrombosis	No	6.2	0.63	15.0	0.21
	Yes	10.1		37.4	
Infiltrative tumor	No	6.7	0.46	19.9	0.57
	Yes	7.6		10.2	

PS	0	9.1	0.14	31.4	0.040
	>0	6.2		9.6	
Child	A5	7.7	0.60	16.4	0.38
	A6	6.0		11.4	

1

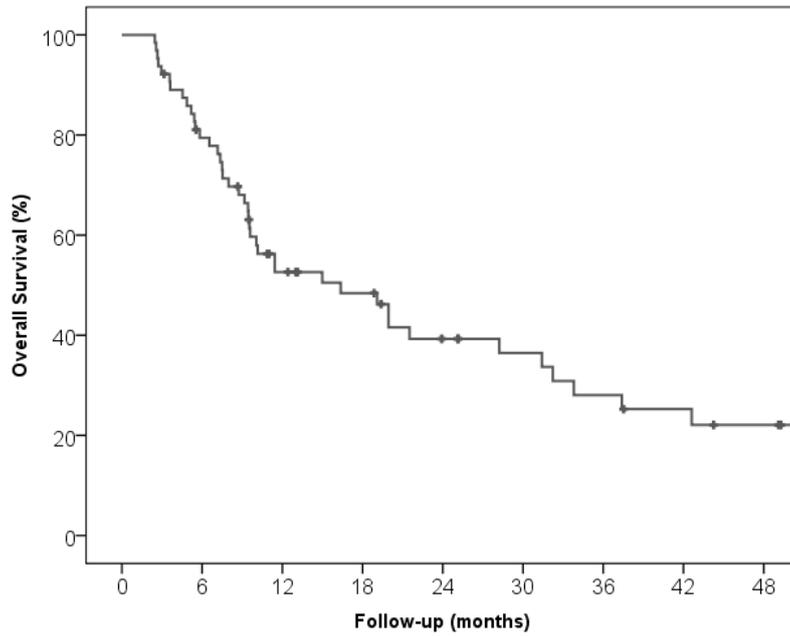

1 Table 4: Incidence of adverse events related to RE:

Adverse Event	Grade 1	Grade 2	Grade 3	Grade 4
Fatigue	7 (11%)	13 (20%)	10 (16%)	0
Liver pain	3 (5%)	10 (16%)	6 (9%)	0
Nausea	0	1 (2%)	2 (3%)	0
Vomiting	0	1 (2%)	0	0
Vascular event	0	0	1	0
Hepatic failure	0	2 (3%)	2 (3%)	0
