ABSTRACT. Passing from fossil energy sources to renewable ones, meanwhile answering the increasing world energy demand, will require innovative and low cost technologies. Smart photovoltaic windows could fulfill our needs in this matter. Their transparency can be controlled to manage solar energy, regulate interior temperature and illumination. Here we present the one-pot synthesis of polymer dispersed liquid crystal (PDLC), in which highly red-NIR phosphorescent transition metal clusters are selectively embedded, either in the polymer, in the liquid crystal or in both phases. The PDLC matrix is used as a tuneable waveguide to transfer the emitted light from nanoclusters to the edge of the device where solar cells could be placed to convert it into electricity. Edge emission is obtained in both “off” and “on” state with a maximum intensity for the scattering “off” one. These doped PDLCs showing photoactivity features and high stability under voltage represent key stepping stones for integration in buildings, displays, and many other technologies.

KEYWORDS. smart window; metal cluster; luminescence; hybrid material; polymer dispersed liquid crystal

INTRODUCTION

Solar energy is, among all renewable energy sources, the most suitable to meet the increasing demand of worldwide energy. Fiscal policies in western countries have led to a high public demand thus dropping down the prices of photovoltaic (PV) solar cells. However, new challenges arise to fulfill the increasing energy demand in particular in highly urbanized locations like megalopolis city centers that are growing vertically. Yet, building rooftops area, where solar panels are usually installed, have become too small to accommodate the necessary amount of PV modules required to insure the building energetic neutrality, as intended now by the EU.¹ Therefore, integrating new innovative PV systems in newly constructs or old buildings meanwhile improving the quality of life of their residents is particularly relevant in our course to the energetic independency and to the ‘zero-energy building’ goal. An efficient strategy to reach this objective is to turn building facades into energy generation units by replacing the actual passive glazing windows with PV systems using efficient luminescent solar concentrators (LSC).²⁻⁵ This technology based on the integration of emissive dyes in a low cost and wave guiding material (glass or polymer) was first developed during the 1970’s.^{6, 7} Sunlight is absorbed by dyes, reemitted at longer wavelength and further concentrated along the edge by internal reflection where PV cells are placed to collect and convert it to energy. Up to now, most of LSCs presented in the literature are static.^{2, 4, 8-12} We propose here a new concept of LSC based on the direct and selective integration of emissive metal nanoclusters into smart windows. Indeed, these “smart windows” could offer several other advantages beside energy production as they gained considerable interest for both privacy and climate control as depicted in **Figure 1**.¹³ They can modulate their transparency to control the spectral and irradiance of incident sunlight, thus regulating interior temperature and adjusting interior room illumination.¹⁴⁻¹⁶ Recently, switchable windows coupled to a LSC additional layer were

1
2
3 described,^{17, 18} as well as self-powered switchable windows based on polymer dispersed liquid
4 crystal (PDLC) technology.¹⁹ Taking into consideration that scattering solar concentrators have
5 also been reported,²⁰ we hypothesized that PDLC could be used to design an all-in-one device and
6 serve as an active waveguiding medium for the light provided by incorporated emitters. As PDLC
7 are biphasic organic materials containing a polymer phase and a liquid crystal phase, we aim also
8 to study the influence of the emitter location (polymer, LC or both phases) on the waveguiding
9 abilities and electro-optic properties of the resulting hybrid matrices. This point is particularly
10 challenging as it cannot be achieved by a simple mixing of dyes within a host matrix but requires
11 additional engineering steps in the design of dyes to target the desired phase. The ideal LSC should
12 contain highly emissive dyes, stable under irradiation and showing a Stokes shift (energy gap
13 existing between the absorption and emission maxima) as large as possible to avoid reabsorption
14 losses, the dominant energy loss mechanism for this technology. According to Traverse et al.,²¹
15 although they do not mention precisely which wavelength area they are dealing with, only Stokes
16 shift higher than 100 nm would allow the production of LSC bigger than 1 m². Octahedral
17 transition metal cluster-based compounds meet all these needs.⁸ Most of them are prepared by
18 solid state techniques as ternary salts of general formula $A_nM_6X^i_8X^a_6$ (A = alkali cation, M=
19 transition metal; Xⁱ: inner ligand; X^a: apical ligand), starting from earth abundant elements and,
20 contain neither cadmium nor lead.²² These phosphorescent inorganic dyes can show an excellent
21 photostability,²³ quantum yield reaching unity,²⁴ possess a very large Stokes shift, and, unlike
22 quantum dots, such Stokes shift is achieved without the need of complex structure engineering.²⁵
23 Several strategies have been employed to bypass their ceramic like behavior by integrating them
24 in various “easy-to-handle” host matrices for large scale and public dedicated devices.²⁶ A
25 prerequisite is their homogeneous embedment in a host material. To do so, inorganic-organic phase

segregation phenomena occurring when interactions between components are not strong enough to maintain a good dispersion must be discarded. Here we show that metal nanoclusters can be integrated in PDLC devices, and that the propagation of their emitted photons can be tuned by applying a low voltage on the device.

Figure 1. Concept of the active LSC window containing red NIR phosphorescent octahedral molybdenum nanoclusters. Schematic exploded representations of an active LSC window composed of a polymer dispersed liquid crystal matrix containing the phosphorescent inorganic emitter, surrounded by PV cells on its edges. The waveguided light and PV cells on the front left of the windows have been omitted for clarity. In the On state, nematic LC molecules contained in the droplets are aligned in the direction of the weak electric field, allowing a good transparency of the window; the material behave like a basic LSC; in the off state, incident sun light is scattered by the randomly aligned LC droplets which increases the waveguiding abilities of the LSC and limits the amount of transmitted light, thus reducing the building internal temperature.

RESULTS AND DISCUSSION

PDLC materials are biphasic organic systems in which a LC material, most commonly a nematic LC, segregates into droplets within a polymer matrix.²⁷ **Figure 2** presents different ways to integrate a metal cluster ternary salt in a PDLC device. It can be introduced in the polymer phase only (case 1), in both phases (case 2), or in the LC phase only (case 3). Here, we use an ionic strategy to control the PDLC doping and homogeneity.^{28, 29} This approach consists of replacing the native inorganic ternary salt alkali cations (usually, Cs⁺ or K⁺ ions) by functional organic ones. Hence organic cations were designed either to copolymerize with targeted organic monomers,^{23, 30} or to confer a nematogenic character to the hybrid assembly so that it becomes miscible with nematic organic liquid crystal mixtures (a mandatory step to avoid LC-LC phase segregation in the nematic LC droplets).³¹⁻³³ All hybrids were synthesized as previously described with conform analytical data.^{23, 32} LC cells of 5 μm thickness were filled up and the mixtures were copolymerized by UV-curing (see experimental section). In all cases, mixtures contained 60 wt% of polymer phase and 40 wt% of LC phase. The amounts of polymerizable nanocluster or clustomesogen (cluster containing liquid crystal, Mo_{LC})^{34, 35} were set to 12 wt% within the polymer phase (Mo@PMMA) and 5wt% in E7 (a commercially available nematic mixture made of cyanobiphenyl- and cyanoterphenyl-containing derivatives, see the experimental section for the exact composition). The LC–polymer phase segregation was then thermally induced³⁶ by heating the cells above the LC to isotropic state transition temperature of liquid crystal mixtures and progressively cooled down to 25°C. All cells were treated at the same time to confer them exactly the same thermal history. **Figure 2** presents the optical micrographs observed under cross polarizers with a white light illumination and a UV irradiation (see **ESI, Figures S1-S4** for full

micrographs and **inset Figure S2** for a SEM micrograph presenting the cross-section of the PDLC film contained in cell 1). LC droplets of 10-25 μm in diameter could segregate from the mixture.

6
7

8
9 Pictures taken under UV irradiation are very informative. They show for cell 1 that there is no
10 emissive species in the LC phase which indicates an optimal phase segregation process from the
11 polymer point of view; for cell 2: the difference observed in the red intensity between the polymer
12 and LC droplets is mainly due to the difference in cluster concentration chosen *a priori* for both
13 phases; for cell 3: a noticeable emission arises also from the polymer matrix showing that part of
14 the doped LC mixture is miscible within the polymer. This partial solubility is well known³⁷ and
15 needs to be taken with care as it implies a variation in the LC mixture components concentration
16 often leading to changes in the transition temperature. Nevertheless, LC droplets emit much more
17 than the surrounding polymer which confirms the higher concentration of clusters in the LC phase.
18 Note that although the same protocol was used in the LC-polymer phase segregation procedure,
19 cell 3's droplets appear smaller and more polydispersed compared to the three other cases.

34 Emission properties were then investigated on the mixtures before and after integration into the
35 cells. Cell 1 was also opened after being filled to observe the influence of air on the emission
36 properties of hybrid matrices. For the sake of comparison, emission properties of neat
37 $\text{Cs}_2\text{Mo}_6\text{I}_8(\text{OCOC}_2\text{F}_5)_6$ cluster are also reported. Steady state emission spectra and time resolved
38 emission studies data are gathered in **Table 1**. Emission lifetime measurements are very instructive
39 about the cluster environment: octahedral clusters are phosphorescent compounds whose triplet
40 excited state reacts efficiently with surrounding triplet oxygen O_2 ($^3\Sigma_g^-$) to generate the reactive
41 and emissive O_2 ($^1\Delta_g$).³⁸ Hence, the $\text{Cs}_2\text{Mo}_6\text{I}_8(\text{OCOC}_2\text{F}_5)_6$ triplet state lifetime decreases from 269
42 μs for a fully deaerated acetone solution to 2 μs for an aerated one.³⁹ The same trend is observed
43 for Absolute Quantum Yield (AQY) values.

Mesogenic clusters emission decay was fitted with two components that is in line with reported results.³² Part of the excited light is absorbed and reemitted by cyanobiphenyl units contained in the mesogenic cations which in turn transfer their energy to clusters. An important decrease of cluster lifetime components values and AQY is also observed when the mesogenic cluster is

1
2
3 dispersed in E7. The lifetime decrease may be assessed to an increased O₂ permeability of the
4 Mo_{LC}/E7 mixture compared to MoLC itself. The AQY decrease comes from the fact that most of
5 the incident light is absorbed by the cyanobiphenyl and cyanoterphenyl units contained in E7 with
6 a poor transfer efficiency to Mo_{LC}. Surprisingly, once integrated in LC cells, the cluster emission
7 lifetime largely increases to reach values in the same range as when clusters are in an oxygen free
8 environment with emission lifetime values higher than 100 μs. This phenomenon is even more
9 appreciable for cell 1 and 2 for which emission decays were fitted by a single exponential with a
10 lifetime value of around 185 μs. When cell 1 was open, its emission decay was fitted with two
11 shorter components. Interestingly, the AQY value of the open cell 1 is around 0.08 under air while
12 it increases to 0.4 under N₂ (value close to the one calculated for the cluster precursor in deaerated
13 acetone solution). Note that this value is higher than the one calculated for Mo@PMMA under a
14 N₂ atmosphere. This is explained by an increased gas permeability of the PDLC matrix compared
15 to the pure PMMA polymer matrix. Exploring the 1200-1400 nm window in air atmosphere for
16 the open cell 1 upon UV excitation revealed the appearance of a signal centered around 1270 nm
17 characteristic of O₂ (¹Δ_g) emission (see ESI, **Figure S5**). The emissive O₂ (¹Δ_g) singlet oxygen is
18 generated by reaction of the cluster triplet excited state with the triplet oxygen O₂ (³Σ_g⁻) contained
19 in the atmosphere which is in good accordance with the shortening of its emission lifetime.³⁸
20 Therefore, calculated lifetimes for the three devices indicate that clusters are in a nearly oxygen
21 free environment that fully exploits their abilities to emit (see ESI, **Figures S6-S12** for emission
22 map and related integrated emission decays). Interestingly, the emission decay of cell 2 could also
23 be fitted with a monoexponential decay. As cell 2 contains clusters in the polymer and LC phases,
24 we could have expected at least the same behavior than for cell 3: an emission decay fitted with
25 two components. The observed monoexponential character reflects the poor contribution of

3 clusters embedded in the LC phase to the total luminescence signal. This is in line with the previous
4 observations on raw material: in the LC droplets, the excitation light is mainly absorbed by the E7
5 host. The reversible changes in the emission lifetime values observed for cell 3 upon voltage
6 application indicates a slight influence of the electric field on the cluster emission properties.
7
8
9

10
11
12 Within a PDLC droplet, LC molecules are usually oriented along the liquid crystal director
13 whose alignment will depend on the voltage applied to the material. Without voltage (OFF state),
14 these LC directors are randomly oriented from one droplet to another, causing a modulation of the
15 refractive index within the material, leading to scattering and to the loss of transparency. In the
16 field-on state, the droplet directors are uniformly aligned along the applied field. In this case, when
17 the ordinary refractive index of LC matches the polymer host refractive index, the material appears
18 transparent.^{40,41} Transmission measurements realized in the OFF and ON states on all cells show
19 that the transmittance is slightly influenced by the cluster concentration. Transmission of undoped
20 cell shows a cut off around 350 nm due to ITO layer and glass support, while an additional
21 shoulder, due to cluster absorption bands, is observed between 350 and 500 nm in doped cells (see
22 ESI **Figures S13-S16**). A maximum transmission value of 85% is achieved through the device in
23 the ON state which is imparted to the inherent optical losses due to Fresnel reflection caused by
24 the differences in refractive indexes at the air/glass/ITO/PDLC/ITO/glass/air interfaces.⁴²
25
26 Therefore, in the ON state, our PDLC material is fully transparent in the cluster emission
27 wavelength range. Although the devices are capable of continuous variation of opacity (see ESI
28 **video S1**), it is important to evaluate how the clusters and polymers influence the E7 native
29 switching properties. Hence transmittance vs applied voltage experiments were realized on all
30 cells. Results are gathered in **Figure 3a**. Similar performances are observed for the control cell
31 and cell 1 whose LC phases contain only E7, as expected. Cell 1 possesses the best $T_{\text{OFF}}/T_{\text{ON}}$

contrast ratio. Doping E7 with 5wt% of clustomesogen does not have a strong impact on the
Fredericksz transition threshold voltage (V_{th} , **table 1**), when the onset of switching of LC
molecules is observed (*i.e.* when the transmittance begins to rise), as reported earlier.³² However,
it has a significant effect on the transmittance vs applied voltage behavior. Indeed, the transition
between the ON and OFF states is not as straightforward when the LC droplets are doped (cell 2
and cell 3) compared to when they only contain E7 (control cell and cell 1). The possible reason
could be that the clustomesogens induce their symmetry up to a certain extent onto the nearest
neighboring LC molecules constituting the unit volume. Their bulkiness imposes the application
of a stronger electric field to align all molecules contained in the LC droplets. Interestingly, we
observed a different behavior under voltage when both polymer and LC phases are doped (cell 2)
compared to cell 3 where clusters were integrated only in the LC matrix. These differences may
originate from an equilibrium between the cluster's "clustomesogen" and "polymerized" forms.
Yet, it cannot be excluded that cationic exchanges occur in the material, and that part of cluster
anions have their dianionic charge counterparted with one polymerized and one mesogenic cation,
in particular at the LC-polymer interfaces. The higher V_{th} value observed for cell 3 is also assessed
to the smaller size of LC droplets which implies a higher driving force to align LC molecules.⁴⁰
Nevertheless, application of a sufficient voltage to turn the devices in the ON state, did not affect
the metal cluster measured lifetime values (**Figure 3d**) which demonstrate the excellent dyes
stability toward the application of an electric field. **Figure 3b** presents the set up used to observe
the emission on the edge of the PDLC cell. The device is continuously excited perpendicularly
with a laser at 448 nm, while applying a 30 V AC 1KHz square voltage in order to observe a full
transmission switch and prevent ionic build-up, which can damage the LC cell.⁴³ The emission is
recorded using a spectrometer or a photodiode focused on the edge with a x20 microscope

objective. The response registered for cell 2 by the photodiode and the spectrometer with or without voltage are given in **Figure 3c** and **Figure 3e**, respectively. These measurements clearly show that the waveguiding abilities of the hybrid PDLC can be tuned. Moreover, as the emission signal is more intense in the OFF state than in the ON one, the waveguiding in the PDLC is more efficient in the OFF state than in the ON one. Hence, a reversible difference of 7%, 16% or 10% of the guided edge-emission intensity was measured in the OFF and ON states for cell 1, cell 2 and cell 3, respectively (see ESI, **Figures S17-S19** for all spectra).

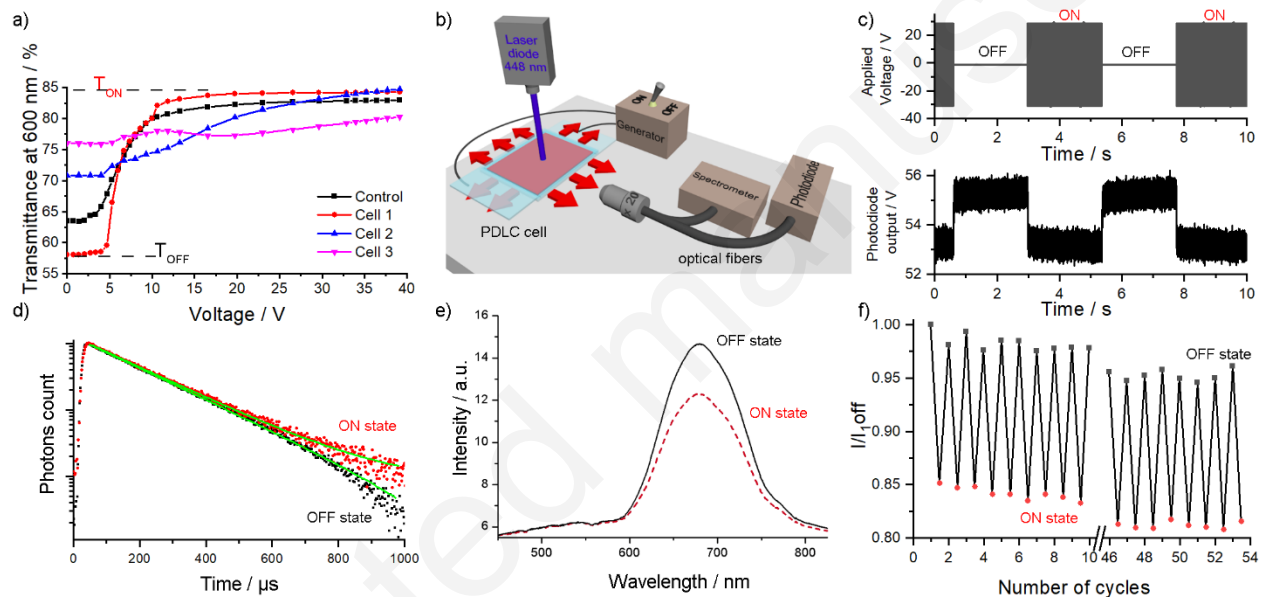

Figure 3. a) Transmittance vs driving voltage; b) schematic representation of the experimental set-up used for the “emission-on-the-edge” measurements. Obtained data for cell 2: c) applied AC voltage and corresponding response of the photodiode vs time; d) integrated emission decay profile and related fitted curves (in green), off (black) and on (red) states; e) emission spectra in the off (plain black line) and on (dashed red line) states; and f) fatigue studies of the edge emission in the off (black) and on (red) states.

1
2
3 From these results, some trends can already be highlighted: in terms of power consumption, cell
4
5 1 prototype seems the most promising device, while cell 2 offers the best contrasts results in terms
6
7 of edge emission. Cycling tests realized under laser excitation on about 50 ON-OFF cycles,
8
9 revealed that these systems are very stable. In all cases, the emission intensity difference between
10
11 the ON and OFF states is maintained after 50 cycles. Best results are obtained for cell 2 with a loss
12
13 of only 2.5% of the emitted intensity at the end of the studies (**Figure 3f and ESI Figures S20-**
14
15 **S22**). The continuous laser excitation during the experiments leads to a local increase of the
16
17 temperature. This affects the refractive index of the PDLC and explains such emission losses.
18
19 However, in all cases, the emission intensity difference between the ON and OFF states is
20
21 maintained. For cell 2, cycling tests were also conducted with the photodiode on 170 cycles (see
22
23 ESI **Figure S23**) without noticing any damages, indicating the high electrical and environmental
24
25 stability of the PDLC cells. At this stage, we wish to emphasize that the devices described herein
26
27 remain proof-of-concept devices. Therefore, depending on environmental factors, parameters such
28
29 as driving voltage, light transmission and waveguiding abilities can be optimized. Indeed, the
30
31 nature of the polymer and LC phases, their ratio in PDLC, the droplets size that influences the
32
33 ON/OFF contrast in transmittance and the driving voltage,⁴⁴⁻⁴⁸ and the cluster nature and
34
35 concentration are belonging to the main parameters that affect the device efficiency. Our efforts in
36
37 optimizing all these parameters will be reported in due course.

47 CONCLUSIONS

48
49 This work describes the first example of hybrid organic inorganic PDLC in which the inorganic
50
51 nanofillers location is fully controlled. We have demonstrated how nanocluster compounds could
52
53 be integrated in such biphasic material to design active luminescent solar concentrators for smart
54
55
56

1
2
3 photovoltaic windows. By associating the inorganic polyanion with specifically designed organic
4 cations, we showed that the emitters could be selectively introduced in the polymer, LC or both
5 organic phases. The hybrid features high photo- and electrical- stability and fully reversible and
6 tuneable waveguiding performances, which are key requirements for successful integration into
7 diverse applications. In the on-state, our devices are transparent and behave like typical static LSC,
8 while in the off-state, their transparency disappears and their waveguiding abilities increase
9 notably. The best waveguiding contrast values are observed when the polymer and LC phases
10 contain the emitter while the best electro-optical properties are obtained when only the polymer
11 phase is doped. The described integration technique has the potential to be extended to other types
12 of metal based clusters showing different emission-absorption properties. Our results indicate that
13 octahedral metal clusters are not only ideal for low-cost, eco-friendly and smart solar cell
14 concentrators, but also possess an excellent stability for switchable optoelectronics.

3
4
5
6 **Emission measurements.** Lifetime measurements and TRPL mapping were realized using a
7
8 picosecond laser diode (Jobin Yvon deltadiode, 375 nm) and a Hamamatsu C10910-25 streak
9
10 camera mounted with a slow single sweep unit. Signals were integrated on a 30 nm bandwidth.
11
12 Fits were obtained using origin software and the goodness of fit judged by the reduced χ^2 value
13
14 and residual plot shape. Absolute quantum yields in the solid state and in solution were measured
15
16 with a C9920-03G Hamamatsu system. O_2 ($^1\Delta_g$) measurements were realized with a Hamamatsu
17
18 H12397-75 NIR-PMT unit mounted on a IHR3 spectrometer. Excitation of thin films was realized
19
20 with a 375 nm laser diode (Jobin Yvon deltadiode). Luminescence spectra in the liquid crystal
21
22 phases were recorded with an Ocean Optics QE65000 CCD spectrophotometer by irradiating the
23
24 samples directly on the microscope hotstage with a Nikon-INTENSILIGHT C-HGFI (UV 1 or
25
26 UV2 filters). Cycling tests were performed by vertical optical coupling using continuous-wave
27
28 448 nm excitation. The optical setup is based on a vertical microscope with an objective x8
29
30 (NA=0.25). The pump spot (diameter = 3 mm) is focused in the centre of the cell (power = 2.8mW).
31
32 Edge emission was collected with an objective x20 (NA=0.30) at one of the slab edges, optimized
33
34 thanks to a visible camera and analysed by a spectrometer or a photodiode. Photoluminescence
35
36 spectra was recorded 10 seconds after switch (ON or OFF) was applied. No reabsorption process
37
38 or shift of the emission band was observed after more than 100 repeated ON/OFF cycles. Voltage
39
40 was provided by a homemade generator providing a tuneable AC square waved voltage (1 kHz).
41
42 When the edge emission of the cell was collected on a photodiode, the emission was analyzed vs
43
44 time temporal on an oscilloscope. The cycling consists of alternation of 30 seconds ON-OFF cycle
45
46 (1h40 experiment, 100 cycles). The ON state consists of 1 kHz square voltage signal with peak
47

55
56
57
58
59
60

1
2
3 amplitude of 30 V_{pk} and average voltage of 0 V_{avg}. The voltage is applied by a function generator
4
5 followed by a high voltage amplifier.
6

7 **Mesomorphism studies.** Mesomorphism was studied by hot stage polarizing microscopy using
8
9 a Nikon polarized optical microscope equipped with a Linkam THMS600 hot stage, a TMS94
10
11 temperature controller, a Nikon -DSFi2 camera.
12
13

14 SEM analysis were realized in the CMEBA –UMS 2001 ScanMat with a JEOL JSM 7100 F
15
16

17 **Preparation of the PDLC cells.** All Preparations were realized in normal atmosphere. The
18
19 monomer/LC mixtures were heated at 60°C to obtain homogenous samples. Blends were then
20
21 injected by capillarity into LC cells deposited on a hotplate at 60°C. The LC cells were then cured
22
23 by UV irradiation at 365 nm (4 W) for 1 hour. Homogenous opaque red-luminescent (under UV)
24
25 mixtures were obtained. To induce the liquid-crystal/polymer phase segregation, the cells were
26
27 heated up to 80°C and cooled at 20°C/min to 61°C. After 5 min at 61°C, cells were cooled to room
28
29 temperature following several cooling rates: from 61°C to 56°C at 0.1°C/min, from 56°C to 52.5°C
30
31 at 0.05°C/min, from 52.5°C to 50°C at 0.1°C/min, from 50°C to 40°C at 0.5°C/min and from 40°C
32
33 to 20°C at 1°C/min. This segregation procedure was performed twice. The phase segregation was
34
35 then controlled by polarized optical microscopy and UV irradiation as depicted in Figure S1-4.
